

AGROMETEOROLOGICAL BULLETIN

The Weather of March 1988

Summary:

The influence of high pressure was greatest to 12th; Atlantic southwesterlies dominated for much of the remainder of the period. The month was very wet (except in the southwest), mild and dull.

Meteorological Situation:

Initially, high pressure in the North Atlantic and active troughs over the North Sea produced rainbelts which moved southwards over Ireland but later fronts approached from the west as pressure intensified over Europe. After the 6th extensions of the high over Ireland yielded to occasional frontal passages, in particular rainfall was especially heavy and extensive on 9th. The general decline of high pressure on 12th allowed active frontal passages go west from 13th to 15th. A ridge from the north on 16th preceded the establishment of a southwesterly airflow and a succession of frontal waves and rainbelts to 26th. Subsequent conditions were changeable, the most notable event being heavy rain in southwestern areas on 29th at the passage of a trough centre.

Precipitation:

Amounts were very much above normal almost everywhere. These varied from 220% of normal at Clones to over 150% generally but only 68% at Dungarvan. Wettest days were 9th, 13th to 15th, 17th/18th, 22nd to 25th and in southwestern areas on 29th.

Temperature:

Mean air temperature varied from 1.1°C above normal at Shannon Airport to 0.7°C above at many coastal stations. Positive night-time deviations, reaching a maximum of 1.9°C at Shannon Airport, were especially large. Soil temperatures peaked in the five-day spell 16th to 20th (1.5°C to 2.5°C above average). Air frost was widespread to 5th and occurred in some places on 10th, 17th and 29th. Ground frost occurred more frequently and was severe in a few places on 5th and 10th.

Sunshine and Radiation:

Bright sunshine hours varied from 91% of normal at Dublin Airport to 63% at Malin Head. It remained dull up to the 20th. Global radiation varied from 97% of normal at Valentia to 74% of normal at Dublin Airport.

Wind:

Gales or general gale gusts occurred on 15th, 24th and 25th. Otherwise gale gusts occurred on 1st, 3rd, 6th, 16th, 22nd to 26th and 29th/30th.

NOTE: The data contained in this bulletin are provisional. Some of the material in Table 1 will be published in its final form in the Monthly Weather Report; final values of Global Radiation at stations in Table 2 will be published in the annual Solar Radiation Observations.

WEATHER AND GRASS GROWTH DURING WINTER (part 1)

Noel Culleton, Johnstown Castle, Co. Wexford.

Autumn management influences date of commencement of growth in the following spring. To all outward appearances growth in winter is at a standstill, everything appears to be dormant. In reality, this is far from the case. There is almost continual leaf formation and leaf death, with new leaves being formed, and old ones being shed all the time. Tillering also proceeds during winter. Fig 1 gives a schematic presentation of the components of growth during the winter months. Weather, especially temperature, has a profound influence on all these growth processes. To understand how Autumn management influences commencement of spring growth it is worthwhile examining how the growth processes are influenced by climatic conditions.

Fig . 1.

Leaf Growth

New leaves of grass continue to appear throughout the winter. Rate of leaf appearance increases with increasing temperature, but even at temperatures close to freezing, some leaves continue to appear.

The growth or extension of these leaves is also mainly a function of temperature. Fig.2 shows that at temperatures between 0 and 12°C leaf growth increases significantly. Leaf growth is also affected by the time of year in that leaves appear to grow more rapidly after late January than before. At 12°C the Spring growth rate was nearly double the Autumn growth rate. The reason for this is that after a cold spell, the tillers are vernalised i.e. tillers move from the vegetative state to the initial stages of the flowering state and these then have a greater potential growth rate. This largely explains why growth in Autumn is significantly less than growth in Spring, even though temperatures can often be higher.

Generally each grass plant or tiller has 3 leaves, one leaf just appearing, one adult or mature leaf and one dying back or senescing. Leaf senescence is as integral a part of plant growth in winter as is leaf extension. Fig. 3 shows the relationship between temperature and leaf senescence. As temperatures rise, so too, does the rate of leaf senescence. Frost or severe cold, can also cause premature senescence of leaves. This can cause the sward to take a brown appearance. However, within a few weeks new leaves appear and the sward greens up again.

Thus, leaf senescence in the sward is complex, in that there are two distinct types of senescence, one due to the natural turn of the leaves and one due to "winter kill". Senescence like growth is "pre-planned" by the grass, it is an ordered disassembly of cells in the leaf and the nutrients in that leaf are moved to the younger part of the plant. This recycling of the nutrients can be a valuable source of nutrients to the actively growing parts of the plant, especially when nutrient supply is poor. The whole area of recycling within the plant and the effect of nutrients and climate on its efficiency warrants further investigation.

During winter the rate of leaf senescence is broadly similar to the rate of leaf growth and there is therefore no net increase in size of leaves and the overall appearance of the sward stays the same. It was also found in trials at Johnstown Castle, that the size of tillers in spring was the same, regardless of the date of closure in the previous autumn. Thus, differences in commencement of spring growth due to various autumn management practices is not due to sizes of individual tillers.
